EQL Open File Report No. 80-2

April 1980

Water Resource Problems of Energy Projects in the Colorado River Basin

INVESTIGATORS: J.P. Quirk, Professor of Economics
N.H. Brooks, Director, Environmental Quality
Laboratory; James Irvine Professor of
Environmental and Civil Engineering
R.C.Y. Koh, Research Associate in Environmental
Engineering
M.S. Isaacson, Research Engineer, Environmental
Quality Laboratory
E.J. List, Professor of Environmental Engineering
Science
H.S. Burness, Visiting Associate in Economics*
E. Hoffman, Graduate Student, Economics*
N.H. Al-Adhadh, Graduate Student, Economics*

The successful development of western coal and oil shale deposits is dependent, to a significant degree, on the availability of adequate water supplies. EQL is involved in a study of the aggregate effects of various energy activities in the upper Colorado River Basin on downstream water quantity and quality. These activities will tend to reduce the available water in the river, and could increase its salinity, which is already so high as to interfere with downstream domestic and agricultural use.

The study in progress has four essential components. The first of these is an understanding of the river system and probabilistic nature of the natural water flows. Research concerning the first phase is found in Publication 4a and an earlier EQL report, Publication 4b. Publication 4a by Burness and Quirk is a background document describing the institutions, water law, legislation, litigation, rights allocation and historical pattern of water use along the Colorado River. Publication 4b by Jensen gives a computer simulation for predicting both water quantities and quality for the Colorado River System with stochastic

*Former investigator who has left Caltech.

inputs from the tributaries. With uncertainty about future river flows, the model allows probabilistic investigations of various alternative policies for water withdrawals and returns with various operating rules for release of water from the major reservoirs.

The second component (which was the main effort in FY77 and FY78 and is now essentially complete) is the study of the legal, economic and institutional aspects of water use and the definition of alternative water allocations. Due to the level of utilization of the Colorado River, the additional water necessary for energy activities is most likely obtainable in two ways, assuming no importation from other basins: (a) alteration in the current allocations of water, and (b) reductions in evaporation losses, such as through reduction in reservoir storage levels. With respect to possibility (a), it is shown in Publication 4c that the doctrine of appropriative water rights, adopted by all of the Colorado River Basin states, leads to economic inefficiencies due to current restrictions on transfer and sale of water rights. The introduction of competitive markets in water rights would eliminate many inefficiencies and provide the possibility of water for energy activities. Moreover, the appropriate pricing of water would limit certain overuses and provide a source of water for higher valued use in energy activities, Publications 4d and 4e. There are, however, natural barriers, in the form of return flow externalities, to the transfer of water rights. This problem is analyzed and solutions to it are suggested in Publication 4f.

The other possibility of obtaining water for energy activities through reductions in reservoir storage levels and the associated evaporation savings, while technically feasible in the short-run (as shown by Jensen) has been found infeasible as a long-term solution, Publication 4g. This is because, when the river is fully appropriated, the current implicit Bureau of Reclamation (Burec) policy of releasing the expected value of streamflows and limiting aggregate water uses to the same, results in a greatly reduced expected value of storage.

On the other hand, this does not rule out the possibility of an interim solution based on reduced reservoir storage, which could make available as much as 1.0 to 1.5 MAF yearly over a thirty year period until the steady state is attained.

The question of optimal storage is also examined on economic grounds in Publications 4h, 4i, 4j, 4k and 4l. While stored water could be used currently, it also functions to ensure against future shortages. The publications discuss the derivation of optimal release policies as a first step in attacking the problem of arriving at the determination of an optimal "insurance premium" to pay to avoid shortages.

The third component is the estimation of water use and residues resulting from different kinds of energy activities. This component was scheduled for FY 79, but due to the late arrival of FY 79 funds, no work could be done during the past year.

Estimation of water usage and residues from various energy activities is now scheduled for FY 80. It will be accomplished primarily through the results of a literature study. This is the third project component listed above.

Synthesis of the first three project components to predict the aggregate effects on the Colorado River system of various energy development scenarios is the final project component. In it the water demands and residues of various energy developments will be incorporated into the computer simulation model. During this phase of the study, active participation on the part of DOE will be sought in terms of possible energy development scenarios in the Colorado River Basin.

In order to facilitate running the computer simulation model for many possible energy resource development scenarios, the model, which is currently structured for use on an IBM 370 computer will be restructured for use on the Environmental Quality Laboratory's dedicated PDP 11 computer facility.

In addition to water quantities, salinity transport in the Colorado River system will also be studied. The operation of the U.S. Bureau of Reclamation's Colorado River Simulation System (CRSS) Model will be analyzed with emphasis on the salinity modeling. The Caltech model will then be modified in order to correctly determine river salinity.

As a final step, the model giving information on both quantity and quality of river flow could be used in conjunction with the results of the economic analysis to determine possible outcomes of energy development scenarios and how different market arrangements for water rights might influence the outcomes.

An additional activity related to this project element carried out at Caltech in FY 79 was the sponsoring of a conference on western water issues. The conference was held on May 17 and 18, 1979 at Caltech and was attended by over 200 people, primarily from California and the southwest. It was supported in part by a special grant from the Office of Environment of the Department of Energy. Although funding for the conference was outside of the institutional grant framework, many of the presentations dealt with the issue of water supply for energy development which is the focus of this project element. A report on the conference was published and is listed below as Publication 4m.
